Measuring Risk in Fixed Income Portfolios using Yield Curve Models

João F. Caldeira · Guilherme V. Moura · André A. P. Santos

Accepted: 25 March 2014 / Published online: 12 April 2014

Abstract We propose a novel approach to measure risk in fixed income portfolios in terms of value-at-risk (VaR). We obtain closed-form expressions for the vector of expected bond returns and for its covariance matrix based on a general class of dynamic factor models, including the dynamic versions of the Nelson-Siegel and Svensson models, to compute the parametric VaR of a portfolio composed of fixed income securities. The proposed approach provides additional modeling flexibility as it can accommodate alternative specifications of the yield curve as well as alternative specifications of the conditional heteroskedasticity in bond returns. An empirical application involving a data set with 15 fixed income securities with different maturities indicate that the proposed approach delivers accurate VaR estimates.

Keywords Dynamic conditional correlation (DCC) · Dynamic factor models · Value-at-risk (VaR) · Yield curve

1 Introduction

Value-at-risk (VaR) is now established as one of the most important risk measures designed to control and to manage market risk and to determine the amount of

capital subject to regulatory control (see Berkowitz and O'Brien 2002; Santos et al. 2012). The use of VaR as a risk measure has become standard in the specialized literature and also widely implemented by most financial institutions. The Basel II and Basel III Accords, for instance, explicitly recognize the role of VaR as a risk measure that financial institutions must implement and report in order to monitor their market risk, which is defined as the risk of losses on positions in equities, interest rate related instruments, currencies and commodities due to adverse movements in market prices. VaR further plays a role in determining the amount of capital subject to regulatory control. Moreover, the Basel Accords also establish penalties for inadequate models and, consequently, create incentives to pursue accurate VaR estimates.

Not only because of the Basel accords, but also because of its popularity in the industry, VaR has attracted a considerable amount of attention from theoretical and applied researchers. A large number of recent studies have sought to find the most appropriate approach to model, and forecast the VaR of a portfolio of assets through backtesting a set of alternative specifications, and checking whether the number of VaR violations is adequate (see Christoffersen et al. 2001; Brooks and Persand 2003; Giot and Laurent 2004; Bauwens et al. 2006; McAleer 2009, among others). These studies, in general, focus on two main approaches to obtain the portfolio VaR. The first uses a multivariate model for the system of individual asset returns and the second models portfolio returns directly using a univariate specification. More recently, Santos et al. (2013) compared both approaches and conclude that the multivariate approach provides more accurate VaR estimates.

The vast majority of the existing evidence on VaR modeling focus on measuring the risk of equity portfolios (see, for example,Engle and Manganelli 2004; Galeano and Ausin 2010). Surprisingly, the literature on VaR modeling of fixed income securities is very thin. This seems to be an important gap in the literature since fixed income securities play a fundamental role in the composition of diversified portfolios held by institutional investors. Among the few references, Ferreira (2005) models the expected returns of the French and German short rates using an autoregressive specification and alternative specifications to model the variances and covariances of the two rates. Ferreira and Lopez (2005) consider the problem of modeling and forecasting the VaR of an equally-weighted portfolio of short-term fixed-income positions in the U.S. dollar, German deutschemark, and Japanese yen using alternative range of multivariate volatility specifications. Alternatively, Vlaar (2000) considers the VaR computation of Dutch fixed-interest securities with different maturities using historical simulation, Monte Carlo simulation methods and a set of univariate volatility models, including univariate models with alternative distribution assumptions. However, none of the existing evidence on VaR modeling for fixed-income portfolios employ factor models for the term structure, neglecting not only the forecast capabilities of this class of models, but also its ability to parsimoniously model high-dimensional applications involving a large number of fixed income securities.

Our approach significantly differs from the existing ones as it is built upon a general class of well established term structure factor models, which have been successfully employed in forecasting yields (see, for instance, Pooter 2007; Diebold and Rudebusch 2011; Rezende and Ferreira 2011 for an analysis of the predictive performance of factor models for the term structure). Moreover, since it is based on factor specifications, our approach is parsimonious and suitable for high-dimensional applications in which a large number of fixed income securities is involved. We use dynamic factor models for the yield curve to derive estimates for the vector of expected bond returns, and alternative GARCH-type specifications to model its covariance matrix, allowing us to obtain out-of-sample VaR estimates of a portfolio of bonds. Finally, we show the flexibility of the proposed approach to model the yield curve as it is able to accommodate a wide range of alternative specifications for the yield curve and also for its conditional heteroskedasticity.

We provide empirical evidence of the applicability of the proposed approach by considering a data set composed of constant-maturity of the Brazilian Inter Bank Deposit Future Contract (DI-futuro), which is one of the most liquid interest rate markets in the world (293 million contracts worth US$ 15 billion were traded in 2010). A total of 16 alternative specifications based on the dynamic version of the Nelson-Siegel model proposed by Diebold and Li (2006) and on its four factor variant proposed by Svensson (1994) are used, and their performance evaluated by means of a backtesting analysis based on independence, unconditional coverage and conditional coverage tests of Christoffersen (1998). These tests, though appropriate to evaluate the accuracy of a single VaR specification, can provide ambiguous decision about which candidate model is better (Santos et al. 2013). Therefore, we also compare the predictive performance among several candidate models applying the comparative predictive ability (CPA) test proposed by Giacomini and White (2006). Our results indicate that the proposed approach is able to deliver accurate VaR estimates for all VaR levels considered in the paper. In particular, we find the VaR estimates obtained with the Nelson-Siegel model with factor dynamics given by a vector autoregressive specification, and conditional covariance matrix given by a dynamic conditional correlation (DCC-GARCH) model, to be the most accurate among all specifications considered and for three VaR levels considered in the paper.

The paper is organized as follows. Section 2 describes the factor models used for modeling the term structure, as well as the econometric specification for the conditional heteroscedasticity of the factors, provides closed-form expression for the first two conditional moments, and presents the methodology for VaR computation. Section 3 discusses the estimation strategy whereas Sect. 4 presents an empirical applications. Finally, Sect. 5 brings concluding remarks.

2 Value-at-risk using Yield Curve Models

In this section we consider the use of dynamic factor models for the yield curve to obtain VaR estimates. Factor models for the term structure of interest rates allow us to obtain closed form expressions for the expected yields, as well as for their conditional covariance matrix. From these moments, we show how to compute the distribution of bond prices and bond returns, which will later be used as an input to compute the VaR of a portfolio of bonds.

2.1 Dynamic Factor Models for the Yield Curve

We consider a set of time series of bond yields with N different maturities $\tau = [\tau_1, \ldots, \tau_N]'$. The yield at time t of a security with maturity τ_i is denoted by $y_{i,t}$ for $t = 1, \ldots, T$ and $i = 1, \ldots, N$. The $N \times 1$ vector of all yields at time t is given by

$$y_t = [y_{1,t},\ y_{2,t},\ \ldots\ ,\ y_{N,t}]', \quad t = 1, \ldots, T.$$

The general specification of the dynamic factor model is given by

$$y_t = \Lambda(\lambda, \tau) f_t + \varepsilon_t, \quad \varepsilon_t \sim NID\,(0, \Sigma_t)\,, \quad t = 1, \ldots, T, \tag{1}$$

where $\Lambda(\lambda, \tau)$ is the $N \times K$ matrix of factor loadings, f_t is a $K-$dimensional stochastic process, ε_t is the $N \times 1$ vector of disturbances with conditional covariance matrix given by Σ_t. As usual in the yield curve literature, we restrict the covariance matrix Σ_t to be diagonal (see, for example,Diebold and Li 2006; Diebold et al. 2006). The dynamic factors f_t are modeled by the following stochastic process:

$$f_t = \mu + \Upsilon f_{t-1} + \eta_t, \quad \eta_t \sim NID\,(0, \Omega_t)\,, \quad t = 1, \ldots, T, \tag{2}$$

where μ is a $K \times 1$ vector of constants, Υ is the $K \times K$ transition matrix, and Ω_t is the conditional covariance matrix of the disturbance vector η_t, which is independent of the vector of residuals ε_t $\forall t$.

The specification for f_t is general. Therefore, it is possible to model its dynamics using a variety of process (see Jungbacker and Koopman 2008). In modeling yield curves the usual specification for f_t is a vector autoregressive process of lag order 1 (Diebold et al. 2006).The specifications considered in this paper are the two main variants of the original formulation of the Nelson and Siegel (1987) factor model, namely the dynamic Nelson-Siegel model proposed by Diebold and Li (2006), and the 4-factor extension proposed by Svensson (1994), which are widely used by central banks and other market participants as a model for the term structure of interest rates (BIS 2005; Gimeno and Nave 2009). Academic studies provide evidence that these models can also be a valuable tool for forecasting the term structure (see Diebold and Rudebusch 2011).

The alternative specifications considered are all nested and can therefore be captured in the general dynamic factor model formulation in (1) and (2) with different restrictions imposed on the loading matrix $\Lambda(\lambda, \tau)$. More specifically, denoting the ith line of $\Lambda(\lambda, \tau)$ by $\Lambda(\lambda, \tau_i)$, the dynamic Nelson-Siegel model implies that:

$$\Lambda(\lambda, \tau_i) = \left[1, \left(\frac{1 - e^{-\lambda\tau_i}}{\lambda\tau_i}\right), \left(\frac{1 - e^{-\lambda\tau_i}}{\lambda\tau_i} - e^{\lambda\tau_i}\right)\right], \tag{3}$$

which means that f_t will be a 3×1 VAR(1).

The model proposed by Svensson (1994) includes another exponential term with a different decaying parameter. The fourth component can be interpreted as a second curvature and allows Svensson's model to fit term structure shapes with more than one local maximum or minimum along the maturity spectrum. The ith line of $\Lambda(\lambda, \tau)$ for the Svensson model is given by:

$$\Lambda(\lambda, \tau_i) = \left[1, \left(\frac{1 - e^{-\lambda\tau_i}}{\lambda\tau_i}\right), \left(\frac{1 - e^{-\lambda\tau_i}}{\lambda\tau_i} - e^{\lambda\tau_i}\right), \left(\frac{1 - e^{-\lambda_2\tau_i}}{\lambda_2\tau_i} - e^{-\lambda_2\tau_i}\right)\right], \quad (4)$$

where λ_2 is the second decay parameter governing the fourth factor.

2.2 Conditional Covariance of the Factor Models for the Yield Curve

Forecasting volatility of interest rates remains an important challenge in financial econometrics.[1] In fixed income applications, this issue is particularly important since interest rate hedging and arbitrage operations are influenced by the presence of time-varying volatility as, in these operations, it is often necessary to compensate for the market price of interest rate risk. Some recent approaches designed to incorporate the presence of conditional heteroskedasticity in the term structure of interest rates have been proposed by Bianchi et al. (2009), Haustsch and Ou (2012), and Koopman et al. (2010).

In this paper, the effects of time-varying volatility are incorporated using a multivariate GARCH specification proposed by Santos and Moura (2011). To model Ω_t, the conditional covariance matrix of the factors in (2), alternative specifications can be considered, including not only multivariate GARCH models but also multivariate stochastic volatility models (see Harvey et al. 1994; Chib et al. 2009). In this paper, we consider the dynamic conditional correlation model (DCC) proposed by Engle (2002), which is given by:

$$\Omega_t = D_t \Psi_t D_t, \quad (5)$$

where D_t is a $K \times K$ diagonal matrix with diagonal elements given by $h_{f_{kt}}$, which is the conditional variance of the k-th factor, and Ψ_t is a symmetric correlation matrix with elements $\rho_{ij,t}$, where $\rho_{ii,t} = 1$, and $i, j = 1, \ldots, K$. In the DCC model, the conditional correlation $\rho_{ij,t}$ is given by:

$$\rho_{ij,t} = \frac{q_{ij,t}}{\sqrt{q_{ii,t} q_{jj,t}}}, \quad (6)$$

where $q_{ij,t}$, are the elements of Q_t, which follows a GARCH-type dynamics:

$$Q_t = (1 - \alpha - \beta)\,\bar{Q} + \alpha z_{t-1} z'_{t-1} + \beta Q_{t-1}, \quad (7)$$

where $z_{f_t} = (z_{f_{1t}}, \ldots, z_{f_{kt}})$ is the standardized vector of returns of the factors, whose elements are $z_{f_{it}} = f_{it}/\sqrt{h_{f_{it}}}$, $\bar{Q}$ is the unconditional covariance matrix of z_t, α e β are non negative scalar parameters satisfying $\alpha + \beta < 1$.

[1] See Poon and Granger (2003) and Andersen and Benzoni (2010) for recent surveys on volatility forecasting.

To model the conditional variance of the measurement errors ε_t in (1), we assume that Σ_t is a diagonal matrix with diagonal elements given by $h_{t\varepsilon_i}$, where $h_{t\varepsilon_i}$ is the conditional variance of ε_i. Moreover, a procedure similar to Cappiello et al. (2006) is applied and alternative specifications of the univariate GARCH type are used to model $h_{t\varepsilon_i}$. In particular, we consider the GARCH model of Bollerslev (1986), the asymmetric GJR-GARCH model Glosten et al. (1993), the exponential GARCH (EGARCH) model of Nelson (1991), the threshold GARCH (TGARCH) model of Zakoian (1994), the asymmetric exponent GARCH (APARCH) model of Ding et al. (1993), asymmetric GARCH (AGARCH) model of Engle (1990), and the non-linear asymmetric GARCH (NAGARCH) model of Engle and Ng (1993). In all models, without loss of generality, their simplest form is adopted in which the conditional variance depends on one lag of both past returns and conditional variances. In all cases, the choice of the specification used is based on Akaike Information Criterion (AIC). The same procedure is applied to the choice of the GARCH specification for the conditional variance of the factors in (5).

2.2.1 Benchmark Models

In order to provide evidence of the flexibility of the proposed approach, we consider alternative conditional correlation specification to model the covariance matrix of the factors in (5). Our first benchmark specification is the constant conditional correlation (CCC) model of Bollerslev (1990). In this case, we consider that the correlation matrix Ψ_t in (5) is constant over time. Our second benchmark specification is the dynamic equicorrelation (DECO) model proposed by Engle and Kelly (2009), which belongs to the class of conditional correlation model but uses a more parsimonious specification in comparison to the DCC model discussed above. In the DECO model, the conditional correlation matrix Ψ_t is given by:

$$\Psi_t = \Psi_t^{DECO},$$

where Ψ_t^{DECO} is the conditional equicorrelation matrix defined as:

$$\Psi_t^{DECO} = (1 - \psi_t^{equi}) I_n + \psi_t^{equi} J_n,$$

where ψ_t^{equi} is the equicorrelation at time t, I_n is a N-dimensional identity matrix, and J_n is a $N \times N$ matrix of ones. Following Engle and Kelly (2009), the DECO sets the equicorrelation ψ_t^{equi} equal to the average pairwise DCC correlation. The model is estimated using the two-step procedure proposed by Engle and Sheppard (2001).

Our second class of benchmark specifications to compute the VaR uses the same expressions for vector of expected bond returns and for the covariance matrix of bond returns discussed in Sect. 2 but replaces the matrices Σ_t and Ω_t in (1) and (2), respectively, with their sample counterparts. In other words, this benchmark specification considers that Σ_t and Ω_t are sample covariance matrices. This is an interesting benchmark to our approach since we originally adopt more sophisticated multivariate and univariate GARCH-type specifications to model these two matrices.

2.3 Expected Bond Returns and the Conditional Covariance Matrix of Bond Returns

As we discuss in Sect. 2.4, the computation of the VaR requires estimates of the expected return of each bond, as well as the covariance matrix of the set of bond returns in the portfolio. However, the factor models for the term structure of interest rates discussed above are designed to model only bond yields. Nevertheless, it is possible to obtain expressions for the expected bond return and for the conditional covariance matrix of bond returns based on the distribution of the expected yields.

It is easy to see from the system of equations in (1) and (2) that the distribution of expected yields $y_{t|t-1}$ is $N(\mu_{y,t}, \Sigma_{y,t})$, where

$$\mu_{y,t} = \Lambda f_{t|t-1} \qquad \text{and} \qquad \Sigma_{y,t} = \Lambda \Omega_{t|t-1} \Lambda' + \Sigma_{t|t-1}, \tag{8}$$

where $f_{t|t-1}$ represents the one-step-ahead forecast of the factors, $\Sigma_{t|t-1}$ and $\Omega_{t|t-1}$ are one-step-ahead forecasts of the conditional covariance matrices in (1) and (2), and we have omitted the dependence of Λ on λ and τ.

Given the distribution of yields above it is possible to derive the distribution of expected fixed-maturity bond prices. Taking into account that the price of a bond at time t, $P_t(\tau)$, is the present value at time t of \$1 receivable τ periods ahead, and letting $y_{t|t-1}$ denote the one step ahead forecast of its continuously compounded zero-coupon nominal yield to maturity, we obtain the vector of expected bond prices $P_{t|t-1}$ for all maturities:

$$P_{t|t-1} = \exp\left(-\tau \otimes y_{t|t-1}\right), \tag{9}$$

where $\otimes$ is the Hadamard (elementwise) multiplication. Since $y_{t|t-1}$ follows a Normal distribution, $P_{t|t-1}$ has a log-normal distribution. Note also that the log-return for a given bond with maturity τ_i can be written as:

$$r_{i,t} = \log\left(\frac{P_{i,t}}{P_{i,t-1}}\right) = \log P_{i,t} - \log P_{i,t-1} = -\tau_i \left(y_{i,t} - y_{i,t-1}\right). \tag{10}$$

The expression above allows us to find a closed form expression for the vector of expected returns of bonds as well as for their conditional covariance matrix. Given (10) and (8), the vector of expected log-returns for bonds, $\mu_{r_{t|t-1}}$, and their conditional covariance matrix $\Sigma_{r_{t|t-1}}$, are given by:

$$\mu_{r_{t|t-1}} = \mathrm{E}_{t-1}[r_t] = -\tau \otimes (\mathrm{E}_{t-1}[y_t] - y_{t-1}) = -\tau \otimes \mu_{y,t} + \tau \otimes y_{t-1}, \tag{11}$$

$$\Sigma_{r_{t|t-1}} = \mathrm{Var}_{t-1}[r_t] = \tau\tau' \otimes \mathrm{Var}_{t-1}[y_t] = \tau\tau' \otimes \left[\underbrace{\Lambda \Omega_{t|t-1} \Lambda' + \Sigma_{t|t-1}}_{\Sigma_{y,t}}\right], \tag{12}$$

where $\Sigma_{r_{t|t-1}}$ is guaranteed to be positive by the Schur product theorem.

The results in (11) and (12) show that it is possible to obtain closed form expressions for the expected bond log-returns and their covariance matrix based on yield curve models such as the ones by Nelson and Siegel (1987) and Svensson (1994). These estimates are key ingredients to the computation of the VaR of a portfolio of bonds.

As pointed out by Litterman and Scheinkman (1991), the return on a fixed maturity zero-coupon bond can be decomposed into two parts. The first part is a result of the capitalization received due to ageing of the bond and the second part is attributed to the change in market prices of constant maturity bonds. Furthermore, Litterman and Scheinkman (1991) point out that the first part is deterministic, while the second part is subject to uncertainty regarding the changes in prices. Clearly, portfolio optimization is only concerned with the second part.

However, for comparison with other benchmarks, it is also necessary to compute the deterministic part of return. The total return is given by the income generated by the capitalization based on the interest rate on the bond, plus capital appreciation given by the variation in market prices. Following Jones et al. (1998) and Goeij and Marquering (2006), the total return (between t and $t+h$) on a bond with fixed maturity τ is given by:

$$R_{t+h}(\tau) = \frac{P_t(\tau)}{P_{t-h}(\tau)} - 1 + \frac{h}{252} y_{t-h}(\tau) = \exp(r_{y,t+h}) - 1 + \frac{h}{252} y_{t-h}, \quad (13)$$

where h is given on weekdays and $r_{y,t+h}$ is the log-return generated by changes in yields of fixed maturities from period t to $t+h$.

2.4 VaR Computation

We now consider the computation of the VaR for bond portfolios using the yield curve models discussed before. As we show next, the closed form expressions for the vector of bond portfolio returns and its covariance matrix discussed in Sect. 2.3 can be applied to the computation of the bond portfolio VaR in a straightforward way. Throughout the paper, we focus on the portfolio VaR for a long position in which traders have bought fixed income securities and wish to measure the risk associated to a decrease in their market prices. In this sense, we are interested in measuring the risk associated to increases in bond yields, which is related to decreasing prices, and thus to negative returns. Moreover, we consider an equally-weighted portfolio, which has been extensively used in the empirical literature; see, for instance, Zaffaroni (2007), DeMiguel et al. (2009), and Santos et al. (2013).

We denote $R_{t+h} = (r_{1,t+h}, \ldots, r_{N,t+h})'$ the vector of h-period returns (between t and $t+h$) of the N bonds included in the portfolio. The bond portfolio return is given by $r_{p,t+h} = w_t' R_{t+h}$, where w_t is the vector of portfolio weights to be determined at time t. The portfolio VaR at time t for a given holding period h and confidence level ϑ is given by the ϑ-quantile of the conditional distribution of the bond portfolio return. Thus, $\mathrm{VaR}_t(h, \vartheta) = F^{-1}_{p,t+h}(\vartheta)$, where $F^{-1}_{p,t+h}$ is the inverse of the cumulative distribution function of $r_{p,t+h}$. Throughout the paper we focus on the portfolio VaR for a holding period of $h = 1$ day at $\vartheta = 1\,\%$, $\vartheta = 2.5\,\%$, and $\vartheta = 5\,\%$, which are the most common risk levels used to compute the VaR. Therefore, from now on, we omit the arguments h and ϑ from the definition of the VaR.

When the distribution of bond log-returns is expressed in terms of its two first conditional moments, the portfolio return can be represented as

$$r_{p,t+1} = \mu_{p,t+1} + \sigma_{p,t+1} z_{p,t+1}, \tag{14}$$

where the standardized unexpected returns $z_{p,t+1}$ are independent and identically distributed with mean equal to zero and unit variance. $\mu_{p,t+1}$ and $\sigma_{p,t+1}$ are the conditional mean and standard deviation of the bond portfolio return, given by

$$\mu_{p,t+1} = w_t' \mu_{r_{t+1}} \tag{15}$$

and

$$\sigma^2_{p,t+1} = w_t' \Sigma_{r_{t+1}} w_t, \tag{16}$$

where $\mu_{r_{t+1}}$ is the $N \times 1$ vector of conditional mean returns for the N individual assets and $\Sigma_{r_{t+1}}$ is their $N \times N$ conditional covariance matrix defined in (11) and (12), respectively. The portfolio VaR is then given by

$$\text{VaR}_{t+1} = \mu_{p,t+1} + \sigma_{p,t+1} q, \tag{17}$$

where q is the ϑ-quantile of the distribution of $z_{p,t+1}$. The closed form expressions for the vector of bond portfolio returns and its covariance matrix in (11) and (12), respectively, can be readily applied to the computation of the bond portfolio VaR in (17).

3 Estimation Procedure

The faster and most straightforward approach to estimate the factors and parameters of the system of Eq. (1) and (2) consists of a two-step procedure proposed by Diebold and Li (2006), where the parameter λ_t is treated as fixed. This treatment greatly simplifies the estimation procedure, after fixing λ_t, it is trivial to estimate β_{1t}, β_{2t}, and β_{3t} from Eq. (3) via ordinary least squares (OLS) regressions. In the first step, the measurement equation is treated as a cross section for each period of time, and OLS is employed to estimate the factors for all time periods individually. Given the estimated time-series for the factors, the second step then consists of modeling the dynamics of the factors in (2) by fitting either a joint VAR(1) model, or by estimating separate AR(1) models. To simplify the estimation procedure, Diebold and Li (2006) suggest reducing the parameter vector by setting the value of λ_t on a priori specified value, which is held fixed, rather than treating it as an unknown parameter.[2]

[2] All models are estimated using a recursive expanding estimation window. Departing from the first 500 observations, all models are estimated and their corresponding one-step-ahead VaR estimated are obtained using (17). Next, we add one observation to the estimation window and re-estimate all models and obtain another one-step-ahead estimate of the VaR. This process is repeated until the end of the data set is reached. In this way, we obtain 486 out-of-sample one-step-ahead VaR forecasts. All results discussed in Sect. 4.2 are based solely on out-of-sample observations.

The decay parameters are estimated nonlinear least squares by minimizing the sum of squared fitting errors of the model. That is, for a given set of estimated parameters the model-implied yields $y_t = \Lambda(\lambda, \tau) f_t$ are computed, and then the sum

$$Z = \sum_{t=1}^{T} \sum_{i=1}^{N} \left(\hat{y}_t(\tau_i) - y_t(\tau_i)\right)^2$$

is minimized with respect to λ.

Although being possibly less efficient than a joint estimation of all model parameters in a one-step maximum likelihood procedure, the two-step approach provides unbiased and consistent estimates of the factors. Moreover, it has the clear advantage that it is fast and thus much better suited for the recursive out-of-sample forecast exercise carried out in this paper.

To obtain the conditional covariance matrix of the factors, $\Omega_{t|t-1}$, a DCC specification in (5) is used. The estimation of the DCC model can be conveniently divided into volatility part and correlation part. The volatility part refers to estimating the univariate conditional volatility models of the factors using a GARCH-type specification. The parameters of univariate volatility models are estimated by quasi maximum likelihood (QML) assuming Gaussian innovations.[3] The correlation part refers to the estimation of the conditional correlation matrix in (6) and (7). To estimate the parameters of the correlation matrix, we employ the composite likelihood (CL) method proposed by Engle et al. (2008). As pointed out by Engle et al. (2008), the CL estimator provides more accurate parameter estimates in comparison to the two-step procedure proposed by Engle and Sheppard (2001) and Sheppard (2003), especially in large problems.

4 Empirical Application

In order to illustrate the applicability of the proposed estimators for the vector of expected bond returns and their conditional covariance matrix, in this section we consider the problem of the one-step-ahead VaR forecasting of an equally-weighted bond portfolio as discussed in Sects. 2.3 and 2.4. As we noted above, our interest is on the portfolio VaR for a long position in which traders have bought fixed income securities and wish to measure the risk associated to a decrease in their market prices.

4.1 Data

Our data set consists of time series of yields of Brazilian Inter Bank Deposit Future Contract (DI-futuro), which is one of the largest fixed-income markets among emerg-

[3] A review of issues related to the estimation of univariate GARCH models, such as the choice of initial values, numerical algorithms, accuracy, and asymptotic properties are given by Berkes et al. (2003), Robinson and Zaffaroni (2006), Francq and Zakoian (2009) and Zivot (2009). It is important to note that even when the normality assumption is inappropriate, the QML estimator of univariate GARCH models based on maximizing the Gaussian likelihood is consistent and asymptotically normal, provided that the conditional mean and variance of the GARCH model are correctly specified, see Bollerslev and Wooldridge (1992).

ing economies, collected on a daily basis. The DI-futuro contract with maturity τ is a zero-coupon future contract in which the underlying asset is the DI-futuro interest rate accrued on a daily basis, capitalized between trading period t and τ.[4] The contract value is set by its value at maturity, $R\$100,000.00$, discounted according to the accrued interest rate negotiated between the seller and the buyer. A similar data set is also used by Almeida and Vicente (2009).

The Brazilian Mercantile and Futures Exchange (BM&F) is the entity that offers the DI-futuro contract and determines the number of maturities with authorized contracts. In general, there are around 20 maturities with authorized contracts every day. In 2010 the DI-futuro market traded a total of 293 million contracts corresponding to US$ 15 billion. The DI-futuro contract is very similar to the zero-coupon bond, except for the daily payment of marginal adjustments. Every day the cash flow is the difference between the adjustment price of the current day and the adjustment price of the previous day, indexed by the DI-futuro rate of the previous day.

We use time series of daily closing yields of the DI-futuro contracts with highest liquidity ranging from January 2006 to December 2010 ($T = 986$ observations). In practice, contracts with all maturities are not observed on a daily basis. Therefore, based on the observed rates for the available maturities, the data were converted into fixed maturities of 1, 3, 6, 9, 12, 15, 18, 21, 24, 27, 30, 33, 36, 42 and 48 months, using the cubic splines interpolation method originally proposed by McCulloch (1971, 1975) [5].

Figure 1 displays a three-dimensional plot of the data set and illustrates how yield levels and spreads vary substantially throughout the sample. The plot also suggests the presence of an underlying factor structure. Although the yield series vary heavily over time for each of the maturities, a strong common pattern in the 15 series over time is apparent. For most months, the yield curve is an upward sloping function of time to maturity. For example, last year of the sample is characterized by rising interest rates, especially for the shorter maturities, which respond faster to the contractionary monetary policy implemented by the Brazilian Central Bank in the first half of 2010. It is clear from Fig. 1 that not only the level of the term structure fluctuates over time but also its slope and curvature. The curve takes on various forms ranging from nearly flat to (inverted) S-type shapes.

---

[4] The DI-futuro rate is the average daily rate of Brazilian interbank deposits (borowing/lending), calculated by the Clearinghouse for Custody and Settlements (CETIP) for all business days. The DI-futuro rate, which is published on a daily basis, is expressed in annually compounded terms, based on 252 business days. When buying a DI-futuro contract for the price at time t and keeping it until maturity τ, the gain or loss is given by:

$$100.000\left(\frac{\prod_{i=1}^{\zeta(t,\tau)}(1+y_i)^{\frac{1}{252}}}{(1+DI*)^{\frac{\zeta(t,\tau)}{252}}}-1\right),$$

where y_i denotes the DI-futuro rate, $(i-1)$ days after the trading day. The function $\zeta(t,\tau)$ represents the number of working days between t and τ.

[5] For further details and applications of this method, see Hagan and West (2006) and Hayden and Ferstl (2010).

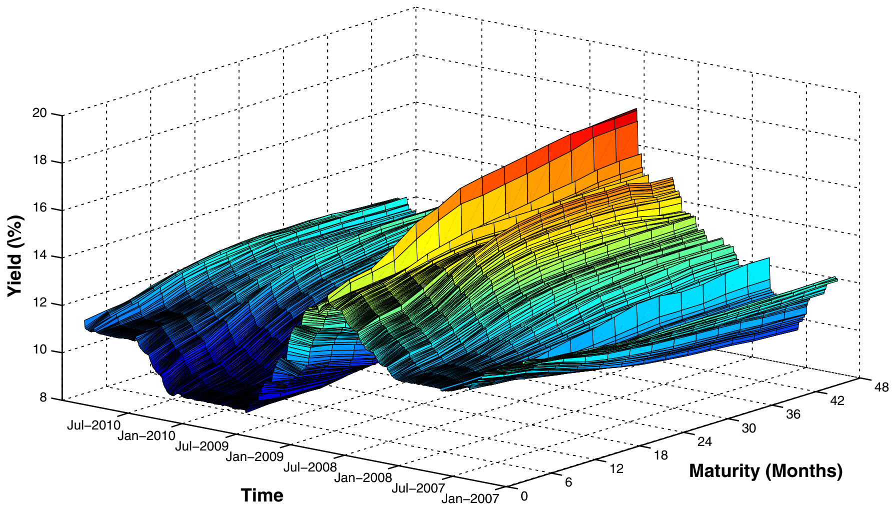

Fig. 1 Evolution of the *yield curve*. The figure *plots* the evolution of term structure of interest rates (based on DI-futuro contracts) for the time horizon of 2006:01–2010:12. The sample consisted of the daily yields for the maturities of 1, 3, 4, 6, 9, 12, 15, 18, 24, 27, 30, 36, 42 and 48 months

4.2 Results

In this section, we report the backtesting results of the VaR estimates obtained with the specifications for the vector of expected bond returns and their conditional covariance matrix proposed in Sect. 2.3. In order to facilitate the exposition of the results, we denote by NS-AR-DCC and NS-VAR-DCC the VaR estimates obtained when the 3-factor Nelson-Siegel model is used to model bond yields and an AR(1) and VAR(1) specifications, respectively, are used to model the factor dynamics and a DCC-GARCH specification is used to model the covariance matrix of the factors. Similarly, we denote by Svensson-AR-DCC and Svensson-VAR-DCC the VaR estimates obtained when the 4-factor Svensson model is used to model bond yields and an AR(1) and VAR(1) specifications, respectively, are used to model the factor dynamics and a DCC-GARCH specification is used to model the covariance matrix of the factors. We also consider the cases in which the covariance matrix of the factors in (2) is modeled according to a CCC and DECO specifications. Finally, we consider the case in which the covariance matrix of the factors in (2) and the covariance matrix of the residuals from the yield model in (1) are sample estimates. Details of these benchmark specifications are given in Sect. 2.2.1.

A important issue related to VaR modeling is the backtesting, which is the analysis of past VaR violations, see Christoffersen (1998), Christoffersen et al. (2001), and Andersen and Bollerslev (2006). This analysis is based on the hit sequence, which is a sequence of binary variables that denotes VaR violations and can be defined as

$$I_t = \begin{cases} 1 & \text{if} \quad r_{p,t} < VaR_t \\ 0 & \text{if} \quad r_{p,t} > VaR_t \end{cases},$$

where $r_{p,t}$ is the bond portfolio return at time t. Clearly, the behavior of the hit sequence is of main interest. Risk managers are concerned with VaR violations and, equally importantly, with whether these violations are clustered in time or if they appear to be randomly sparse. Clustered violations indicate that the VaR model can be misspecified and can fail to predict the portfolio VaR in times of high volatility such as during financial crises. For risk measurement purposes, the accuracy of VaR estimates during financial turmoils is highly desirable. Christoffersen (1998) points out that the problem of determining the accuracy of the VaR can be reduced to the problem of determining whether the hit sequence satisfies two properties. The first is the unconditional coverage property, which states that the probability of realizing a loss in excess of the reported VaR must be precisely $\vartheta \times 100\,\%$. To check if this is the case, one has to compute the empirical (or realized) hit rate, which is the number of times in which the observed bond portfolio returns is lower than the estimated VaR over the total number of periods analyzed, i.e. hit rate $= \frac{1}{T}\sum_{t=1}^{T} I\left(r_{p,t} < VaR_t\right)$. For instance, when computing the VaR at the 1 % nominal level, one would expect that in 1 % of the cases the observed portfolio return should be lower than the estimated VaR (i.e. a hit rate of 1 %). The second aspect is the independence property, which indicates whether two elements of the hit sequence are independent from each other. Intuitively, if previous VaR violations presage a future VaR violation then this points to a general inadequacy in the reported VaR measure. In order to test for these desired properties, we adopt in this paper the approach proposed by Christoffersen (1998). The approach consists in using the hit sequence to test for independence, unconditional coverage, and conditional coverage (joint test for independence and unconditional coverage).

Table 1 reports the the hit rate and the p-values of the independence, unconditional coverage and conditional coverage tests for the 1, 2.5, and 5 % VaR estimates obtained with each of the specifications proposed in the paper. We find that some specifications passed *all* backtests in the three VaR levels considered. For instance, when looking at the VaR estimates for the 1 % level, we observe that the NS-VAR-DCC and NS-VAR-CCC passed all backtests. These specifications achieved an exact empirical coverage rate of 1 %. The VaR estimates delivered by the Svensson-AR-DCC specification also performed well, with an empirical coverage rate of 1.2 %. As for the VaR estimates for the 2.5 % level, we find once again that the NS-VAR-DCC and NS-VAR-CCC performed remarkably well as they passed all backtests. Finally, as for the VaR estimates for the 5 % level we find that five specifications passed the correct unconditional coverage tests, but only the NS-VAR-DCC and NS-VAR-CCC specifications passed joint conditional coverage test. These results suggest that these specifications deliver extremely accurate VaR estimates for the bond portfolio considered in the paper and provide favorable evidence to the proposed estimators for the vector of expected bond return and its covariance matrix proposed in the paper.

It is worth noting that the independence, unconditional coverage, and conditional coverage tests, though appropriate to evaluate the accuracy of a single model, may not appropriate for ranking alternative estimates of the VaR and can provide an ambiguous decision about which candidate model is better. Therefore, it is interesting to enhance the backtesting analysis by using statistical tests designed to evaluate the comparative performance among candidate models, see Santos et al. (2013) for a discussion. In this

Table 1 Backtesting results

The table reports the backtesting results for the VaR estimates at the $\vartheta = 1\,\%$, $\vartheta = 2.5\,\%$, and $\vartheta = 5\,\%$ levels obtained with the specifications for the vector of expected bond returns and their conditional covariance matrix proposed in the paper. We report the hit rate and the p-values of the independence ("Indep."), unconditional coverage ("U.C.") and conditional coverage ("C.C.") tests. NS-AR-DCC and NS-VAR-DCC denote the the VaR estimates obtained when the 3-factor Nelson-Siegel model is used to model bond yields and an AR(1) and VAR(1) specifications, respectively, are used to model the factor dynamics and a DCC-GARCH specification is used to model the covariance matrix of the factors. Similarly, Svensson-AR-DCC and Svensson-VAR-DCC denote the VaR estimates obtained when the 4-factor Svensson model is used to model bond yields. A similar notation applies to the remaining specifications. We highlight in bold the p-values indicating the non-rejection of the null hypothesis of the test

sense, we follow Santos et al. (2013) and consider the CPA test proposed by Giacomini and White (2006). Consequently, on top of evaluating whether each of the estimated VaRs are adequate, we also compare and rank them by implementing the CPA test of Giacomini and White (2006) which can be applied to the comparison between nested and non-nested models and among several alternative estimation procedures.

The p-values of the Giacomini and White (2006) CPA test for each pairwise comparison among all specifications considered in the paper corroborate the backtesting results discussed above. The NS-VAR-DCC specification outperforms all other specifications in all cases. In a few cases, however, the differences in performance with respect to other specifications are not significant. For instance, the difference with respect to the NS-VAR-CCC specification is not statistically significant. This suggests that both NS-VAR-DCC and NS-VAR-CCC performed very well in modeling the VaR for the bond portfolio.

5 Concluding Remarks

Obtaining accurate risk measures are an important issue in risk management. In this sense, the use of VaR as a risk measure plays a major role in monitoring market risk exposure and determining the amount of capital subject to regulatory control. The vast majority of the existing evidence on VaR modeling focus on measuring the risk of equity portfolios. Therefore, in this paper we contribute to the literature on VaR-based risk measurement by putting forward a novel approach to measure risk in bond portfolios. Our approach significantly differs from the existing ones as it is built upon a general class of well established term structure factor models such as the dynamic version of the Nelson-Siegel model proposed by Diebold and Li (2006), and the four factor version proposed by Svensson (1994). We derive closed-form expressions for the vector expected bond returns and for the covariance matrix of bond returns based on yield curve models to compute the VaR of a bond portfolio.

We provide an empirical application by considering a data set composed of constant-maturity future contracts of the Brazilian Inter Bank Deposit Future Contract (DI-futuro) which is equivalent to a zero-coupon bond and is highly liquid. Based on the estimates for the vector of expected returns of these fixed-income assets and their conditional covariance matrix, we obtain out-of-sample VaR estimates for an equally-weighted bond portfolio and provide a comprehensive backtesting analysis. Our results indicate that the proposed specifications outperform several benchmark specifications in modeling and forecasting the one-step-ahead VaR at different levels.
